ABSTRACT

Background Restrictions on mobility have been implemented by many countries to limit the spread of novel coronavirus infection (COVID-19) yet have important social and economic consequences. Their impact on reducing transmission is, however, inadequately understood.

Methods We examined the association of COVID-19 incidence rates with mobility changes, defined as changes in categories of domestic location, against a pre-pandemic baseline, using country-specific daily incidence data on newly confirmed COVID-19 cases and mobility data collected from mobile devices in all 34 OECD countries plus Singapore and Taiwan. The study period was from the day of the 100th case in each country to August 31, 2020. Daily incidence rates were lagged by 14 days and regressed to mobility changes using LOESS regression and logit regression.

Findings In two thirds of examined countries, reductions of up to 40% in commuting mobility (to workplaces, transit stations, retailers, and recreation) were associated with decreased COVID-19 incidence, more so early in the pandemic. However, these decreases plateaued as mobility remained low or decreased further. We found smaller or negligible associations between mobility restriction and incidence rates in the late phase in most countries.

Interpretation Mild to moderate degrees of mobility restriction in most countries were associated with reduced incidence rates of COVID-19 that appear to attenuate over time, while some countries exhibited no effect of such restrictions. More detailed research is needed to precisely understand the benefits and limitations of mobility restrictions as part of the public health response to the COVID-19 pandemic.

Funding none

How well does societal mobility restriction help control the COVID-19 pandemic? Evidence from real-time evaluation

INTRODUCTION

One of the most widely implemented policy response to the novel coronavirus (SARS-CoV-2) pandemic has been the imposition of restrictions on mobility (1). These restrictions have included both incentives, encouraging working from home, supported by a wide range of online activities such as meetings, lessons, and shopping, and sanctions, such as stay at home orders, restrictions on travel, and closure of shops, offices, and public transport (2-5). The measures constitute a major component of efforts to control the COVID-19 pandemic. Compared to previous epidemic responses, they are unprecedented in both scale and scope (6).

The rationale underpinning these public health measures is that restricting normal activities decreases the number, duration, and proximity of interpersonal contacts and thus the potential for viral transmission. Transmission simulations using complex mathematical modelling have built on past experience such as the 1918 influenza epidemic (7), as well as assumptions about the contemporary scale and nature of contact in populations (8). However, the initial models were not always founded on empirical evidence from behavioral scientists on the feasibility or sustainability of mass social and behavior change in contemporary society. While reductions in interpersonal contact and increases in physical distancing are known to decrease respiratory infection spread (9), the paucity of recent examples of large-scale restrictions on mobility has limited the scope for research on their impact on transmission. Where restrictions have been imposed, as with Ebola, they have involved diseases with a different mode of transmission. Nonetheless, the rapidity of progression of this pandemic has forced many governments into trialing various approaches to containment with limited evidence of effectiveness⁽¹⁰⁾.

More conventional public health prevention measures (such as quarantine of contacts, isolation of infected individuals and contact tracing) and control measures in health systems (such as patient flow segregation, negative pressure ventilation, and use of personal protective equipment) (11-14), have been applied widely to control the epidemic in many countries as part of a portfolio of policy responses. However, mobility restriction as a new large-scale mass behavioral and social prescription has incurred considerable costs (15, 16). Estimates suggest global GDP growth has fallen by as much as 10% (17), at least in part due to mobility restriction policies. Although views differ, not least because of the lack of information of what would happen if the disease was unchecked and the emerging evidence of persisting disability in survivors, some have argued that this is greater than would be accounted for by the economic impact of direct illness and deaths from COVID-19 (18, 19).

To inform decisions on large scale restrictions of mobility, there is an urgent need to assess their effectiveness in limiting pandemic spread. To this end, we examined the association of mobility

with COVID-19 incidence in Organization of Economic Cooperation and Development (OECD) countries and equivalent economies such as Singapore and Taiwan.

METHODS

Study population and data

The study population consisted of the populations of 36 countries (all 34 OECD countries plus Singapore and Taiwan). Two sets of publicly available data were pooled into one dataset: country-specific newly confirmed COVID-19 cases per day retrieved from the dataset curated by *Our World in Data* (<https://ourworldindata.org/coronavirus>) (20), and country-specific mobility change data obtained from the *Google Global Mobility Data Source* (21, 22).

Variables

Independent variables

We used country-specific mobility data, collected from mobile device-based global positioning system (GPS) information from people who agreed to share their anonymized position information with Google, starting from the date the 100th case was detected in a country. The average mobility around specific categories of locations during the reference period (between January 3 and February 6, 2020, a period before COVID-19 was declared a global pandemic) was applied as a baseline mobility value for each country to calculate the percent mobility change on each day during the study interval for each country. The data were categorized by Google into 6 different types of locations visited (workplaces, transit stations, retailer and recreational places, residential areas, groceries and pharmacies, and parks). To reduce multicollinearity, three highly correlated variables (workplace mobility, transit station mobility, and retailer and recreation mobility) were averaged into a combined latent variable (“commuting mobility”) as the main mobility variable for this study, as this is the activity that is most likely to bring large groups of people together. The correlation analysis of different types of mobility is shown in Supplementary Fig 1.

Outcome variables

The outcome variable chosen was the daily national incidence rate of new COVID-19 cases (daily new cases per accumulated cases over the prior 14 days), intended to reflect the total number of local active infections on that day, starting from the 14th day from the date the 100th case was detected in each country through August 31, 2020.

Analysis

First, daily incidence rates of COVID-19 and mobility changes during the study period were described. Second, the daily national COVID-19 incidence rates were compared to changes in mobility. The analysis sought any country-specific associations between COVID-19 daily incidence rate and the percentage change in mobility for each of the 36 countries with a 14-day lag using LOESS regression, a nonparametric technique that uses local weighted regression to fit a smooth curve through points in a scatter plot (23). Based on the range and frequency of commuting mobility values observed across countries, we grouped values into mild (up to 20%),

moderate (21-40%) and extensive (greater than 40%) degrees of mobility change, when describes various degree of associations per each mobility change. Logit-transformed incidence rates were regressed to mobility changes to compare the country-specific association using a single regression coefficient per each country. We performed additional analysis by designating an early phase versus late phase using the median date (between the day of the 100th case and the last day of study period–August 31) for each country; and by using different mobility location categories (i.e. residential areas, parks, or groceries and pharmacies) beyond the main analysis focused on commuting mobility. The unit of analysis was country level. All analyses used R (version 4.0.0, R Foundation for Statistical Computing, Vienna, Austria).

Sensitivity Analysis

We performed sensitivity analyses by varying the lag interval (7 or 21 days) between the change in mobility and incidence of infection to apply various incubation period possibilities.

RESULTS

There were 5,766 observations with data on daily incidence of COVID-19 infections and mobility changes, from 36 countries, starting with the 100th case in each country, which ranged from February 21 (South Korea) to March 23 (New Zealand), and continuing until August 31, 2020. The changes in commuting mobility were pronounced, from a 91.8% decrease (Spain on Apr 10) to a 60.8% increase (Greece on Aug 16). National daily incidence rate of COVID-19 cases was as high as 0.64 (New Zealand on Mar 10). There was a reduction in incidence in most countries as mobility decreased by up to 20% or 40% but, in most cases, then reached a plateau with little further change after additional reductions (Fig. 1 and 2). The degree of association varied, with some countries experiencing relatively small changes in mobility. The magnitude of the association tended to be larger in the earlier period, as shown in Fig. 3 where the country- and phase-specific slopes of the curves (point estimation with 95% confidence interval) are shown using logit regression.

Of note, small increases in mobility in residential areas, seen throughout most of the study period in all countries, were associated with reductions in COVID-19 incidence, but larger increases had no additional effect in the early phase, and there were no associations in any ranges in the late phase (Fig. 4, Fig S2). In the early phase, increased mobility in parks was associated with increased incidence in 5 countries (US, Spain, Japan, Estonia, and Latvia) whereas it was not associated in other countries. In late phase, there was no association in most countries (Fig. 4 and Fig. S2). Mobility around groceries and pharmacies, generally viewed as essential visits, was typically associated with the highest incidence of infection at a time when mobility was close to baseline, during the early phase (Fig. S3). In the late phase, however, this finding no longer held and there was no association between infection rate and mobility, regardless of the degree of mobility change. In fact, results from the late phase show little association between incidence and mobility changes in any locations in most countries, except some for a reduction in incidence with moderate restriction in commuting mobility in Ireland, Australia, Italy, Spain Estonia, and Hungary; and an increased incidence with increased mobility around parks in Estonia, Hungary, and Spain (Fig. 1, 2, 3 and 4; Fig. S3 and S4). The findings were mostly consistent in the

sensitivity analysis, when we used alternative lag periods of 7 or 21 days in the model (Fig. S4).

DISCUSSION

Overall, the expectation that reduced mobility would be associated with reduced incidence of COVID-19 cases was confirmed, at least up to a 20-40% reduction. Further reductions were not associated with significant additional declines in incidence. Mobility restrictions were most effective in the early phase of the pandemic in most countries and much smaller in the later phase.

This study has several limitations. First, Google data are only generated by Android users who have location services switched on. These individuals may be an atypical minority of the population in some countries, or there may be changes in the type of users over time, such as tourists (as in Greece), although in most cases numbers will be small. Second, reported incidence rates are influenced by availability of testing and quality of reporting. Third, the use of an ecological design introduces scope for confounding and imprecision: our data do not allow us to isolate the impact of mobility restrictions from the many other variables that intervene in a pandemic response, such as the degree of inter-household mixing, the ability to detect and rapidly control an outbreak, and behavioral characteristics, such as use of face coverings and adherence to physical distancing guidelines, themselves influenced by clarity of messaging and trust in official advice. A related limitation is that, in federal countries such as the United States, there may be substantial sub-national differences in implementation of these characteristics and in other policies. However, given the complex nature of these relationships, influenced by starting conditions, feedback loops, and non-linear relationships, the analytic challenges of disentangling these factors are formidable even if data were available.

There are a variety of possible explanations for our findings. Mandatory restrictions on mobility may reduce both the frequency and/or duration of interpersonal interactions and, by reinforcing official advice, the nature of those interactions, with greater distancing and hygienic precautions. As restrictions are lifted, protective behaviors such as distancing may have become normalized, mitigating the effects of greater mobility. When this is coupled with improved contact-tracing, quarantine, and support for isolation, the relative benefits of mobility restrictions may decrease as the population adopts additional risk mitigation measures, allowing a return to greater mobility (adapting to the “new normal”). These behavioral changes may also be enhanced through social learning of these practices promoted by trusted and authoritative public health messaging. While this finding supports the role of mobility restrictions as a critical strategy early in a pandemic or when a country has yet to implement more comprehensive and meticulous mitigation strategies, it suggests that rapid scale-up of a suite of other coordinated mitigation strategies simultaneously as part of a strategy to drive transmission as low as possible may maximize health gains while enabling a gradual reopening of the economy (24-28).

These findings are consistent with other research suggesting benefits of early mobility restrictions (29); for example, an earlier study of government-imposed physical distancing interventions demonstrated an association with larger reductions in COVID-19 incidence, although this did not directly assess the degree of mobility reduction nor the impact of timing of the interventions (30). Modeling in China using mobile phone data in the initial phase of pandemic provides further support for this view (31).

Our study uses mobile phone tracking to analyze real-time changes in mobility. In at least some jurisdictions the public seems to have pre-empted official instructions, reacting to emerging data (28)(32). One study in the United States, where implementation of other public health mitigation strategies has varied, found a strong correlation between decreased mobility patterns and lower COVID-19 case growth rates using similar phone tracking data (32).

Our analysis focused on changes in commuting mobility. However, this is only one way in which people mix and spread infections, with inter-household spread important in some settings (33). Although we did find some associations between incidence and, for example, mobility in residential areas, these are difficult to interpret and investigation of these phenomena will require other data sources, such as apps that record close contacts. Finally, our finding of little difference using different lag times (7, 14 or 21 days) is consistent with prior research suggesting a typical lag between interventions and changes in infection rate of around 14 days (32, 34).

While additional work is needed to elaborate on these findings, they may be useful to policymakers as they adapt responses to the pandemic over time and, in particular, point to the importance of including mobility data when developing comprehensive strategies.

CONCLUSION

Our analysis extends the understanding of the complex dynamics at play when mobility is restricted at a population level in response to a pandemic caused by a respiratory virus. Societal mobility restrictions appear to have reduced COVID-19 spread in many countries, particularly in the early phase of the pandemic, but in the late phase, when other measures have been adopted, the impact is less. Additional evidence, including the relationship with other non-pharmacological interventions, is needed to fully understand the role of mass restrictions on mobility in containing COVID-19 and future infectious diseases with a similar mode of transmission. As the pandemic progresses, governments must develop strategies that bear down on the amount of circulating virus and allow rapid responses to outbreaks. The pandemic has brought enormous changes to working and living, some of which will likely persist even if and when a vaccine is made available. Surveillance that goes beyond incidence of infection, to include risk factors such as mobility, can only improve our ability to develop effective public health responses.
